December 28, 2012

Abstract

The allocation of children's time among different activities may be important for their cognitive and non-cognitive development. In our work we exploit time use diaries from the Longitudinal Study of Australian Children to study the effect of time allocation across a wide range of alternative activities. By doing so we characterize the trade-off between the activities to which a child is exposed. On the one hand, our results suggest that time spent in educational activities, particularly with parents, is the most productive input for cognitive skill development. On the other hand, non-cognitive skills appear insensitive to alternative time allocations. Instead, these skills are greatly affected by the mother's parenting style.

*We thank the editor and two anonymous referees for their suggestions. We also wish to thank Frank Wolak, Katrien Stevens, Jennifer Bowes, Olena Stavrunova and seminar participants at the 2012 Australasian Meetings of the Econometric Society, 2010 NBER summer institute, the University of Oxford, the University of Queensland, the University of New South Wales, the University of Sydney, Queensland University of Technology and the University of Wollongong for helpful comments.

1 Introduction

In the last decade a number of studies have found that skills measured at early ages (e.g., age 3 to 6) are strong predictors of later life outcomes such as educational attainment, wages, employment, and choice of occupation; as well as adolescent risky behaviors such as teenage pregnancy, criminal activity, smoking and alcohol use. The factors found to predict later outcomes include both cognitive and non-cognitive skills (e.g., perseverance, motivation, risk aversion, self-esteem). Examples of these findings can be found in the work by Cameron and Heckman (1998, 2001), Keane and Wolpin (1997), Bernal and Keane (2011, 2010), Heckman, Stixrud, and Urzua (2006),Cunha, Heckman, and Lochner (2006).

Given the growing evidence of the importance of early childhood skills for later life outcomes - particularly economic outcomes - there has been a growing interest in investigating the determinants of these skills. Many studies have focused on how early childhood activities, as well as other influences like household income, school quality, child care, etc., affect the development of skills or abilities.

However the current literature is confronted with two main problems. First is the difficulty of measuring all of of a child's activities, not to mention the many other inputs to child development. Second is the empirical problem of distinguishing a mere correlation between activities and skills from a true causal effect. To illustrate this, let us define the production function for skill Y of individual i observed at age a as:

$$Y_{ia} = X'_{i\{K\times a\}}\theta_{\{K\times a\}} + \gamma_a \mu_i + \epsilon_{ia} \tag{1}$$

where X is the matrix of K inputs from age a backwards (the complete history of inputs), μ_i is the innate ability/personality of the child (at age 0) and ϵ is a transitory error term that captures shocks to the child development path. The inputs in X can be time inputs, such as time in school or with parents; goods inputs, such as number of books, intake of calories; and measures of the quality of these inputs, such as, e.g., parental education or teacher-student ratios.

The first problem, measurement of a child's activities, originates from the fact that most surveys include only a limited amount of information about what a child does, where and with whom. As a result, researchers have tended to focus on the effect of just a few of the many inputs into child development, and to group child time into very broad categories, such as time spent with the mother vs. time spent in child care. This is problematic however, because the estimated effect of any input depends on what other inputs are omitted in the equation.

To clarify this point, consider a simple world where a child's time T can only be allocated between child care T_C, time with parents T_P and time watching television alone T_V, so that $T_C + T_P + T_V = T$. For simplicity, consider the special case where time not in child care is equally shared between time with parents and time watching television, so that $T_P = T_V = \frac{T-T_C}{2}$. Finally, let these three time inputs, and a latent ability endowment μ (likely correlated with the time inputs), be all that matter in the development of skill Y, so that the production function is simply $Y_i = \beta_0 + \beta_C T_{iC} + \beta_P T_{iP} + \beta_V T_{iV} + \gamma\mu_i + \epsilon_i$ where ϵ_i is orthogonal to all other variables. A researcher, who has imperfect knowledge of this simple world, but who is interested in the effect of child care on skill Y, might estimate $Y_i = \gamma_0 + \gamma_C T_{iC} + u_i$. Suppose the researcher is able to find a consistent estimator for γ_C such that $p \lim_{N\to\infty} \widehat{\gamma}_C = \gamma_C$, and finds that $\widehat{\gamma}_C > 0$. It is tempting to conclude that child care is good for the child. Yet, it is easy to show that in our simple world $\gamma_C = \beta_C - \left(\frac{\beta_P+\beta_V}{2}\right)$. Thus γ_C is a relative effect. Whether or not child care is beneficial to the child depends on what substitutes for child care.[1]

For instance, let $\beta_C = 2$, $\beta_P = 3$ and $\beta_V = 0$. As a result $\gamma_C = 0.5 > 0$. But spending time in child care increases Y only if child care substitutes for time watching television (since $\beta_C > \beta_V$). In contrast, child care lowers Y if it substitutes for time with parents (since $\beta_C < \beta_P$). This simple world could be generalized to several activities and to goods inputs, where, given a financial constraint, parents substitute one good for another. In any case, the estimated coefficient of the *observed* input captures an effect relative to that of the *unobserved/omitted* inputs that act as substitutes. Thus, when a researcher studies the effect of a few inputs in isolation what we learn might be quite limited or misleading, even if the estimator is consistent.

Our aim is to estimate child (cognitive + non-cognitive) skill production functions with an exceptionally rich set of time and other inputs. To do so we exploit diary data contained in the Longitudinal Study of Australian Children (LSAC), a survey following a cohort of children born in 1999 and surveyed biannually since 2004. The LSAC includes 24-hour diaries where parents provide information about *what* the child is doing, *where* and *with whom*. It also contains very rich data on other inputs to child development.

In the first component of this paper we analyze the diary data to get a better view of how Australian's children spend their time during a typical week. This has a value in itself because there are not many studies documenting children's time use. In the second and main component of our research we link the diary data to cognitive and non-cognitive measures of ability, demographics, and parental background information. This additional data is provided in the LSAC main survey. We then investigate whether alternative time allocations lead to different levels of cognitive and non-cognitive development: e.g. time

[1] More generally, let α be the share of time not in child care that is spent with the parents. Then $T_P = \alpha(T - T_C)$ and $T_V = (1-\alpha)(T - T_C)$. It follows that $\gamma_C = \beta_C - \alpha\beta_P - (1-\alpha)\beta_V$.

with parents vs other adult relatives, time in educational vs. other activities, time with other children vs time using media, etc. Thus, our production function can be expressed as follows:

$$Y_{ia} = TI'_{i\{K\times a\}}\beta_{\{K\times a\}} + PB'_{i\{G\times a\}}\delta_{\{G\times a\}} + e_{ia} \tag{2}$$

where TI is a matrix of K time inputs measured from age a backwards while PB is a matrix of G parental background characteristics (that proxy for both goods inputs and innate ability μ_i) and parenting style measures. The error term e, includes omitted variables, measurement error and shocks to the child development path. We construct the K time inputs such that $\sum_{k=1}^{K} TI_{ia\{k\}} = 168$, the number of hours in a full week.

By explicitly modeling the complete weekly time allocation we are able to rank time inputs according to their productivity: a ranking of the $\beta_{\{a\}}$ vector is informative about how a reallocation of a child's time from "unproductive" (bottom ranked) to "productive" (top ranked) time inputs at age a can enhance skill development. In other words, we characterize the trade-off between *all* alternative activities, home and school, to which a child is exposed.

To our knowledge, this research is the first to estimate the effect of alternative overall time allocations on children's development - as opposed to examining effects of only one or two time inputs in isolation.

As we will see, from an econometric point of view the paper which is closest to ours is Todd and Wolpin (2007). However, their work differs from ours in that they do not attempt to estimate the effects of a range of alternative time allocations and other inputs. Instead, they proxy for a wide range of inputs into child development using the home environment index (HOME) in the US National Longitudinal Survey of Youth. All home inputs are proxied by this scalar index, obtained by adding up responses to a battery of questions about the home environment. In addition, school inputs are proxied by state and county level information on pupil-teacher ratios.

We believe there are three important ways in which our work goes beyond Todd and Wolpin (2007). First, our measures of child inputs are more extensive. Note that the HOME index still fails to measure many important home inputs, such as the amount of time the child spends in activities with mothers and other care givers, the amount of time spent watching TV or playing video games, etc.. Second, our input measures are more concrete. For instance, it is not at all clear what levers a parent or a policy maker would have to pull to move the HOME index. But time in child care, length of the school day, etc. can be altered in obvious ways. Third, we are able to characterize the trade-off between alternative home inputs (e.g. TV time versus parents time), which one cannot do using one scalar HOME input.

The second problem faced by the literature, distinguishing a mere correlation between activities and skills from a true causal effect, is also severe. In equation (1) endogeneity can come in three forms: (1) omitted variables, since we do not observe μ or some of the other inputs in X; (2) simultaneity, if Y causes X and not vice versa (e.g. does reading books make children smarter or, do smart children read more books?); (3) measurement error in X, e.g. it is legitimate to ask whether the parent knows exactly (or truthfully reports) how many hours the child spent reading.

The literature has proposed different estimation strategies to deal with these problems. The papers by Todd and Wolpin (2003, 2007) specify a production function where a test score is a function of home and school inputs together with unobserved initial ability. They then discuss a set of non-nested estimators and the assumptions under which each of these estimators identifies the production function. The set of estimators include OLS, Fixed Effects (within family and within child) and Value Added, among others. They attempt to address the identification problem by comparing results from these different statistical models. Since they have no strong prior on what model best deals with endogeneity, Todd and Wolpin (2007) pick the model that minimizes the out-of-sample root mean-squared error (RMSE). They then focus on inferences from the preferred model.

Our objective is rather different. That is, we will eschew any attempt to choose a "best" model, as any criterion we could use would necessarily be controversial.[2] Rather, our goal is to determine whether there exists a ranking of inputs that is robust across the whole range of the most popular models used in the literature (e.g., value added, fixed effects, etc.). As each estimation method attempts to handle endogeneity in a different way, relying on different maintained assumptions, we would have more confidence in a ranking of inputs that is robust across methods. A robust ranking of the time inputs, if it exists, implies that a reallocation of time use can enhance child development.[3]

The simple example we presented earlier shows that analyzing one input in isolation conveys only partial and potentially misleading information because we cannot characterize the trade-off between inputs. We have argued that this makes it important to try to measure all of a child's activities. Clearly, having multiple endogeneous inputs makes the estimation problem much more difficult. If our model contained just one endogenous in-

[2]For instance, the RMSE criterion used by Todd and Wolpin (2007) chooses the "best" model based on fit, but the best fitting model does not necessarily deal with the endogeneity issues.

[3]The papers by Cunha and Heckman (2007, 2008) propose a different approach in order to investigate the self-productivity and dynamic complementarities between cognitive and non-cognitive skills. They use a system of equations where future cognitive and non-cognitive skills are simultaneously determined by their current level (self and cross), a measure of the current parental investment and unobserved inputs. Identification in their system relies on cross-equation covariance restrictions. We do not replicate Cunha and Heckman (2007, 2008) strategy inasmuch as it is not our aim to uncover self-productivity and dynamic complementarities between cognitive and non-cognitive skills. Moreover we are interested in the effect of several (K) alternative time inputs rather than a one dimensional investment factor.

put, then an instrumental variable or equally suitable quasi-natural experiment approach might be possible. But estimating the β vector in equation (2) by IV requires $K - 1$ exclusion restrictions (as the β on one time input is normalized to 0 for identification). Finding such a large set of valid instruments is not feasible in our application. Therefore, we feel that in rich models like ours it is more practical to deal with endogeneity using other approaches (e.g. fixed effects, value added models) combined with sensitivity analysis.[4]

Our results suggest that time spent in educational activities, particularly with parents, is the most productive input for cognitive skills. A reallocation of children's time which favors these kinds of activities by substituting away from less productive ones would have a positive effect on cognitive skill. This result is robust to different identification assumptions. Perhaps surprisingly, we also find that, for reading skills, media time does not appear to be any worse that other non-educational time uses, like time in before/after school care. However, non-cognitive skills like behavioral problems, social skills and emotional problems appear insensitive to alternative time allocations. Instead, these skills greatly depend on some aspects of parenting style. A style that combines effective (but not harsh) discipline with parental warmth leads to the best non-cognitive outcomes. This finding on parenting style is new in the economics literature.

2 Data

The Longitudinal Study of Australian Children (LSAC) is a biannual survey which began in 2004. The LSAC follows two cohorts of children: one born March 1999-February 2000 (4983 children) and one born March 2003-February 2004 (5107 children). These are known as the "K cohort" and the "B cohort". Both cohorts have been surveyed three times, in 2004, 2006 and 2008 (a fourth survey is currently in the field). Table 1 illustrates the average age at interview for each Cohort/Wave pair.

Table 1: Average Age at Interview

	Wave 1	Wave 2	Wave 3
K Cohort	4 years and 9 months	6 years and 10 months	8 years and 10 months
B Cohort	9 months	2 years and 10 months	4 years and 10 months

[4]We do not mean to say that IV would necessarily be the preferred approach if it were feasible. On the contrary, even if IV were feasible, it would merely provide another alternative method of dealing with endogeneity whose advantages/disadvantages would have to be compared to the other approaches we employ. Like them, IV is not assumption free. The Journal of Economic Perspectives, 2010, 24(2), has an excellent discussion on this topic. The point we are trying to make is that an IV approach is hardly an option in our context.

For both cohorts the survey collected a rich set of information about the children's skills, demographics and parental background. In addition, the LSAC collected time use diaries, where parents recorded their children's activities over 24 hours. As far as we are aware, the only other data set combining information on children's skills/background with time use diaries is the US Child Development Supplement (CDS), a sample of children from households in the PSID. The CDS included time use diaries in 1997 (0-12 year-old children), in 2002 (5-18 year-olds) and in 2007 (10-19 year-olds). Compared to the CDS, LSAC has the advantage of focussing on only two cohorts with a larger sample size. LSAC children are generally much younger than those in the CDS, who were born between 1984-1997. LSAC children are also surveyed biannually in contrast to the five year gap between the two waves of the CDS. This makes the LSAC an excellent data set to analyze early childhood development.

In the rest of the paper we limit our attention to the K Cohort. The data for the younger B Cohort lack consistent measures of skill because of changes in the type of test across waves. This prevents us from using some estimators like Value Added and Fixed Effects.

2.1 Time Use Diaries

The Time Use Diary (TUD) collects details of the activities of the study children in LSAC over two 24-hour periods: one a specified weekday and one a specified weekend day. After the LSAC personal interview, the respondents were left with some self-complete forms, including the Time Use Diaries. The interviewer worked through an example of how to complete the diary with the respondent, and the respondent was advised of the dates for which they should complete the diary. These dates were selected by the interviewer to ensure a random allocation of weekdays and a random allocation of weekend days. The diaries divided the 24-hour day into 96 15-minute intervals.[5]

For each child the diaries classified separately the *activity* (26 alternatives), *where* the activity took place (5) and *who with* (7). Most diaries were completed by the child's mother (approx 91%), with 7% completed by the child's father. The remaining 2% were completed by other family or carers. This is stable across waves.

[5]Parents were given specific dates to fill the diary, like Tuesday-July 26 for the weekday diary and Saturday-July 30 for the weekend diary. They were also asked if they could not complete the diary on their allocated date to wait another week before completing it, such that the completion day was on the same day of the week as was the date selected for them. The objective was to have an even distribution among the 5 weekday days and between the 2 weekend days. We assume the activity recorded in each time period lasted for the full 15 minutes. This may result in an overestimation of time spent in specific activities, when those activities take less than 15 minutes.

2.1.1 Original and Re-coded Time Use

Figure A-1 in the Appendix gives an example of the diary and its coding. This is the example that parents were shown. The diaries did not change between waves 2 and 3. The diary at wave 1 (see figure A-2) is slightly different to account for age specific activities.

If we divide the day into *activities*, *where* they took place and *who* they were with, we would obtain $26 \times 5 \times 7 = 910$ different time use categories. With our sample size it is not feasible to estimate how 910 types of time use affect child development. Thus, our first goal is to re-code the data into a smaller set of categories. We choose to have 9 mutually exclusive time use categories in order to facilitate the analysis while at the same time not losing valuable information. From our investigation of the data, we feel that a manageable list of activities is: (time in)

1. Bed (*bed*);
2. School-Day Care (*sch*);
3. Educational activities with parents (*ped*);
4. Educational activities with adults other than parents (*oed*);
5. General Care with parents (*pcr*);
6. General Care with adults other than parents (*ocr*);
7. Social activities (*soc*);
8. Media (*mda*);
9. Not sure what child was doing (*unk*);

Note that we attempt to distinguish activities that have an educational component from those that involve basic child care, supervision or child rearing. Educational activities include time spent reading a story, being talked to or helping with chores. In contrast, General Care includes activities such as travelling (transportation), being fed or cuddled. We further split these two categories depending on whether they are done with the parents or with other adults. Appendix Tables A-1 and A-2 fully describe our re-coding algorithm.

Note that children could be coded to a number of activities concurrently, so the sum of time spent in different activities may exceed 24 hours. Unfortunately, parents were not asked to differentiate between the main activity being undertaken (primary activity) and any activities being undertaken concurrently (secondary activities). Thus, whenever the parent indicated that the child was in two or more concurrent activities within the same time slot, we assign the slot to what we consider the primary activity. The numbering 1-9 of the time inputs listed above reflects our ordering into primary, secondary and so on. Say, for instance, a child was being fed by the mother (5. General Care with parents) while also watching TV (8. Media). We would code this as General Care with parents since we consider this the primary activity. Also, note that we distinguish between cases where the activity was coded "Not sure what child was doing", an entry in the diary, and cases where the activity is simply missing (which are excluded).

2.1.2 Attrition, Missing Data and Sample Selection

Here we discuss problems with attrition, missing data and sample selection. To simplify the discussion hereafter we use forward slashs to indicate wave 1, wave 2 and wave 3 diary data (w1/w2/w3). In the LSAC there is a total of 6959/6453/5573 diaries for 3728/3385/2906 children. Therefore, diary data is not available for 25% of the original sample of 4983 children at Wave 1. There is additional attrition of 7% between Waves 1 and 2 and 10% between Waves 2 and 3. Attrition in the main survey is 10% between waves 1 and 2, but only 3% between waves 2 and 3. Diaries were left to parents to complete and send back to LSAC administrators, while the main survey was collected with the interviewer present.

Among those parents who filled out a diary, not all returned both weekend and weekday diaries. Since our objective is to investigate time allocation during a week, we exclude these cases. Also, parents were asked to indicated whether the diary was completed on an ordinary day, a holiday, a crisis day, etc. Since we would like the diaries to be as representative as possible of the child's typical time allocation, we exclude diaries filled out on non-ordinary days. We further restrict our sample to diaries filled out within the school term dates.

Also, there are several diaries where not all of the 96 15-minutes slots were assigned to an activity. We choose to keep only complete diaries and do not impute unassigned slots with one exception: slots between 10pm and 6am that are missing or coded "Not sure what child was doing" are re-coded as time in bed sleeping.

Finally, we also drop cases with clear inconsistencies between the main and the diary data. An example is a parent indicating the child is enrolled in school while the weekday diary data shows very low school time, or vice versa.

Table 2 shows the combined effects of attrition, missing data and our other sample screens. Clearly the combined effect on sample size is substantial, as we have usable diaries for 26%, 21% and 12% of the original sample by waves 1, 2 and 3 respectively. Still, we have sample sizes of over 1000 in waves 1 and 2.

We next investigate whether attrition, missing data and our screening criteria lead to sample selection with respect to the original sample. To do so we run a probit model where the dependent variable is equal to 1 if the child is in our sample and zero otherwise. The independent variables are demographic characteristics reported in the main survey. Table 3 presents the results. There is evidence of statistically significant selection on some

Table 2: Diaries completed

	Wave 1		Wave 2		Wave 3

Stars indicate significance at 5% (**) and 10% (*) level.
Max{M Ed, F Ed} = max years of education between mother and father.
Numbers in table are marginal effects calculated at the means, except for Gender (calculated for Girls).

2.1.3 Children's Time Allocation

In this section we describe children's time allocation in our sample using the re-coded activities as described above.

In figure 1 we show the distribution of each time-use category over a 24 hour period (tempogram). We present separate sub-figures for the three waves. We use solid lines to describe weekday patterns, and dashed lines to describe weekend patterns. The vertical axis measures the fraction of children in a specific category, while the horizontal axis shows the time of the day. Note that the vertical axes are not on a common scale across all panels. This makes it easier to see how each time input varies over the 24 hours, but makes it harder to get a sense of how frequent each category is relative to the others. Not surprisingly, School/Day care activities (*sch*) are most frequent between hours 9 and 16. After hour 18 almost no child is in pre-school/day care. Educational activities with parents (*ped*) are widespread throughout the day, but with a mode in the evening (i.e. around hours 19-20). General parental care (*pcr*) is instead multi-modal with peaks in the early morning, lunch time and evening. Both these patterns are intuitive given patterns of meals and bed time reading, lending face validity to the diary data. Social activities (*soc*) are quite widespread throughout day, with higher frequency in the 8-9 and 15-18 time windows. Time using media (*mda*) peaks in the early morning and evening. Bed time has the expected U shape. Because of our coding algorithm there are no children in the "Not sure" (*unk*) category between 22 and 6 on the following day.

Table 4 shows the weekly distribution of time across children. Weekly hours are derived by multiplying the weekday allocation by 5 and the weekend day allocation by 2, and then by summing the two products. As expected there is more variation in school/childcare time at wave 1 (when children are on average 4 years and 9 months old and are therefore attending childcare/kindergarten/pre-school) than at waves 2 and 3 (when children would be attending primary school). Since primary school hours are generally uniform across schools, the variation at waves 2 and 3 is mainly the result of before and after school care time. Time in school seems to reduce time with parents, both in educational or general care activities. It is also evident that both the level and standard deviation of educational and general care activities with other adults are much less than those with parents.

Table 4: Weekly time in each derived activity

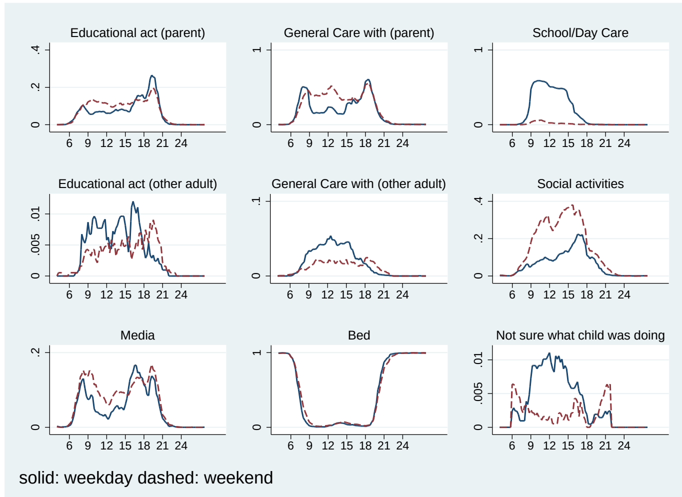
2.2 Children's Skills, Demographics and Parental Background

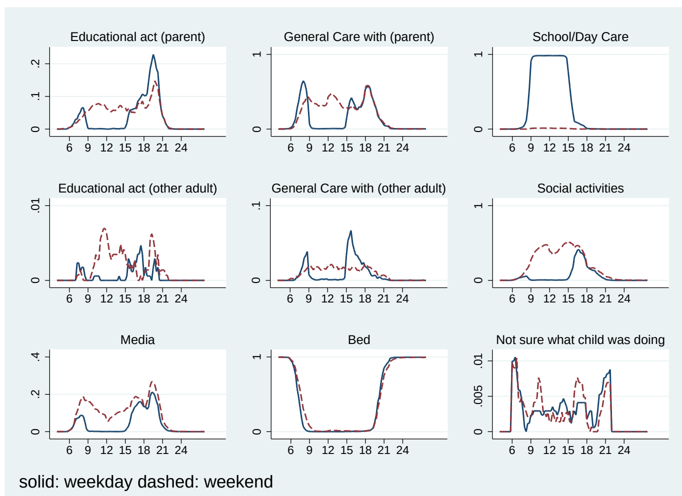
2.2.1 Cognitive and Non-Cognitive Skills

The LSAC children were administered three cognitive skill tests depending on their age.

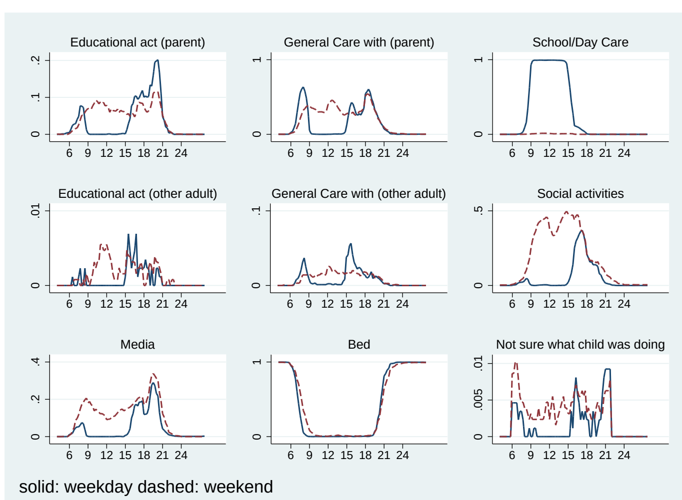
- **Peabody Picture Vocabulary Test** (All Waves) A short form of the Peabody Picture Vocabulary Test (PPVT - III), a test designed to measure a child's knowledge of the meaning of spoken words and his or her receptive vocabulary. Different



(a) Wave 1



(b) Wave 2



(c) Wave 3

Figure 1: Tempogram

versions of the PPVT containing different, although overlapping, sets of items of appropriate difficulty were used for children aged 4-5 years, 6-7 years and 8-9 years. A PPVT stimulus book with 40 plates of display pictures was used. The child is not required to define words but to show what they mean by pointing to (or saying the number of) a picture that best represents the meaning of the word.

- **Matrix Reasoning Test** (Waves 2 and 3) Children completed the Matrix Reasoning (MRT) test from the Wechsler Intelligence Scale for Children, 4th edition (WISC-IV) at ages 6-7 and 8-9 years. This test of non-verbal intelligence presents the child with an incomplete set of pictures (defined by geometric shapes) and requires them to select a picture that completes the set from 5 different options.

- **Who am I? Test** (Wave 1 only) The Who am I? (WAI) is a direct child assessment measure that requires children to copy shapes and write numbers, letters, words and sentences. It is used for the children at ages 4 to 5 to assess general cognitive abilities needed to begin school.

In the analysis we standardize each score to have mean 0 and standard deviation 1.[6]

Non-cognitive skills are measured through parental assessment. In all the three waves parents were asked 25 questions about children's behavior. Answers to each question can take 3 values: 1 Not true; 2 Somewhat true; 3 Certainly true.

Starting from the 25 questions, we construct measures of non-cognitive skill by using iterated principal factor analysis. In table 5 we show the rotated factor loadings.[7] At each wave we retain 3 factors (those whose eigenvalues are larger than one). In the table we shade the factor loadings larger than 0.25 in absolute value: the larger is the factor loading the larger is the correlation between the variables (rows) and factors (columns). The loadings are remarkably stable across waves.

Based on the factor loadings, we interpret the first factor as an index of behavioral problems such as restlessness, over-activity, short attention span and temper problems. The second factor seems to capture empathy, kindness and friendliness. Finally, we interpret the third factor as an index of poor self-esteem, insecurity, shyness and depression (a range of emotional problems). These kind of non-cognitive skills are similar to those

[6]The PPVT and MRT tests are copyright protected and we cannot include an example in the paper. However, we had a chance to see (and even attempt) the tests. Our impression is that they do capture different types of skills. More information about the Peabody Picture Vocabulary Test can be found at `http://www.pearsonpsychcorp.com.au/productdetails/242` (PPVT-4) and information about the Matrix Reasoning Test can be found at `http://www.pearsonpsychcorp.com.au/productdetails/46`

[7]Note that only two questions changed between waves 1 and 2, while between waves 2 and 3 there was no change. In the two cases where the question changed across waves, we show both wave 1 and 2/3 questions separated by a double vertical line ||.

measured by Cunha and Heckman (2008). For clarity, in the rest of the paper we will use a single term to describe each factor, namely

- Factor 1: **Index of behavioral problems**;
- Factor 2: **Index of good relationships with others**;
- Factor 3: **Index of emotional problems**;

Each factor is standardized to have mean zero and standard deviation 1, and ordered so that a higher score corresponds to better non-cognitive skills, i.e. fewer behavioral or emotional problems and better relationships with others.

2.2.2 Other Variables of Interest

The LSAC is a very rich data set. A great deal of information was collected about the child, as well as his/her household, home and school environments. In table 6 we report basic statistics for a few selected variables. The sample is evenly split between girls and boys. Parents were on average in their early thirties at the time of their child's birth, with fathers about two years older than mothers. Father's income is substantially larger than mother's income (as a relatively low proportion of mothers work full-time in Australia). The percentage of indigenous children is unfortunately very small: it was quite difficult to contact and follow those living in remote areas. Table 7 shows mothers' education and the order in the table reflects the ranking of qualifications. Achieving Year 12 is equivalent to graduating from high school. Certificates represent vocational qualifications post high school.

2.2.3 Derived Indicators of Parenting Style

The LSAC questionnaire asked both parents a set of questions describing their behavior towards the child. We identify 17 questions, common across waves, that are related to parenting style (see Table 8, column 1). We factor analyze the answers reported by the mother to derive a concise set of indicators of parenting style.[8]

Table 8 shows the rotated loading coefficients. The factor loadings larger than 0.25 in absolute value are shaded in grey. As with non-cognitive skills, the factor loadings are very stable across waves. We interpret the first factor as an index of mother warmth and affection. The second factor is strongly correlated with situations where the child ignores punishment and the mother has problems managing the child. Therefore, we interpret this factor as an index of the mother's effectiveness in imposing discipline. Note

[8] We only use the mother's answer to account for those children with only 1 biological parent (mostly the mother). We select factors with an eigenvalue larger than 1.2.

that the questions that load on this factor capture not simply lack of discipline, but also inconsistency and harshness in how discipline is imposed (this is why we adopt the description "(in)effective" rather than "lenient"). To help exposition, we change the sign of the second factor, so a large value corresponds to effectiveness. In the rest of the paper we refer to these two factors as

- Factor 1: Index of mother warmth;
- Factor 2: Index of effective mother discipline;

We include these two measures of parenting style in the regression analysis.

We can find only a few papers in economics (Dooley and Stewart (2007), Cosconati (2009), Bjorklund, Lindahl, and Lindquist (2011)) that use these kind of variables when investigating the determinants of child development. Yet the developmental psychology literature has investigated the link between parenting style and skills, particularly the non-cognitive ones, since the early 1960s (see Baumrind (1966), Weiss and Schwarz (1996) and Hart, Newell, and Olsen (2003) for a discussion).

3 Estimation

In equation 2 on page 3, we wrote the production function for child cognitive and non-cognitive development as depending on both time inputs (TI) and parental background characteristics (PB):

$$Y_{ia} = TI'_{i\{K\times a\}}\beta_{\{K\times a\}} + PB'_{i\{G\times a\}}\delta_{\{G\times a\}} + e_{ia}$$

However, identification of equation (2) is complicated by endogeneity of the time inputs (TI). Therefore, we estimate our production function under alternative estimators that attempt to deal with endogeneity in different ways. The estimators we choose are based closely on the discussion in Todd and Wolpin (2003, 2007). Below we briefly review the chosen estimators and their assumptions.

3.1 OLS using Contemporaneous Inputs only (CT)

This is arguably the most common specification in the literature. In this model only current (age a) inputs are included. The estimating equation becomes:

$$Y_{ia} = TI'_{ia\{K\}}\beta_{a\{K\}} + PB'_{ia\{G\}}\delta_{a\{G\}} + e_{ia}$$

where TI and PB are respectively a K vector of observed time inputs and a G vector of parental background characteristics. The key assumptions behind this model are:

- only current time inputs matter;
- $PB_{ia\{G\}}$ is a good proxy for any unobserved inputs as well as innate ability μ_i;

Thus, the OLS estimator relies on a rich set of control variables (PB) to proxy for μ_i, thereby dealing with the endogeneity that arises if allocations are correlated with innate ability. This assumption is arguably more plausible in the LSAC than in most data sets previously used to study child development, because of the very rich set of controls that are collected (particularly the home environment measures).

3.2 Contemporaneous + Lagged Test Score (VA)

This specification is known in the literature as Value-added. It is identical to CT but for the inclusion of the lagged test score as a control variable. Intuitively, the lagged score acts as a proxy for unobserved innate ability μ. The estimating equation becomes:

$$Y_{ia} = TI'_{ia\{K\}}\beta_{a\{K\}} + PB'_{ia\{G\}}\delta_{a\{G\}} + \lambda_a Y_{i,a-1} + e_{ia}$$

Although this specification may seem to be a clear improvement over the contemporaneous one, it also requires some strong assumptions. Namely:

- The effect of inputs (observed or unobserved) declines with age at the rate λ_a;
- The effect of μ_i declines with age at the rate λ_a;

A few steps of algebra are needed to understand these assumptions. For the sake of brevity we refer the reader to Todd and Wolpin (2007) pages 98-99.

3.3 Fixed Effects (FE)

Within child Fixed Effects (or First Differences) is another popular specification whenever longitudinal data are available. The estimating equation becomes:

$$\Delta Y_{ia} = \Delta TI'_{ia\{K\}}\beta_{\{K\}} + \Delta PB'_{ia\{G\}}\delta_{\{G\}} + \Delta e_{ia}$$

Here, one differences out the scalar μ_i rather than attempt to control (or proxy) for it. The key assumptions behind this model are:

- Strict exogeneity of inputs with respect to e_{ia} (i.e. e_{ia-1} cannot affect inputs at a);
- The effect of observed inputs is constant by age;
- The effect of μ_i is constant by age;
- The omitted inputs and their effect are constant with age;

3.4 Contemporaneous + Lagged Inputs (CU)

This specification (also known as the cumulative model) expands the contemporaneous specification to include observable lagged inputs. Thus, it relaxes the assumption that only current inputs matter:

$$Y_{ia} = TI'_{i\{K\times a\}}\beta_{\{K\times a\}} + PB'_{i\{G\times a\}}\delta_{\{G\times a\}} + e_{ia}$$

where TI and PB are now a $K \times a$ matrix of observed time inputs and a $G \times a$ matrix of parental background characteristics. The key assumption behind this model is:

- $PB_{i\{G\times a\}}$ is a good proxy for any unobserved inputs as well as innate ability μ_i

3.5 Contemporaneous + Lagged Inputs + Lagged Test (CV)

This specification is a combination of the cumulative and value-added models. It generalized the value-added model by relaxing the assumption that the effect of observed inputs declines at rate λ_a. The estimating equation becomes:

$$Y_{ia} = TI'_{i\{K\times a\}}\beta_{\{K\times a\}} + PB'_{i\{G\times a\}}\delta_{\{G\times a\}} + \lambda_a Y_{i,a-1} + e_{ia}$$

The key assumption behind this model is now:

- The effect of μ_i and unobserved inputs declines with age at the rate λ_a;

This model was preferred in Todd and Wolpin (2007), as we discuss below.

3.6 Discussion

Among the estimators that we include, CT, VA and CU are nested within CV. Yet as Todd and Wolpin (2003, 2007) point out, it is difficult to argue in favor of any one model unless the researcher has strong priors on the set of assumptions needed to justify each. Most papers present results for a range of estimators, choose a "preferred" model based on some criterion, and then focus on the estimates from that model to draw policy conclusions. For example, in their 2007 paper Todd and Wolpin pick the CV model because it minimizes the out-of-sample root mean-squared error (RMSE).

In contrast, we are not interested in choosing a preferred model per se, as any criterion we might use to do so would necessarily be controversial. Rather, we are interested in whether there exists an estimator-robust ranking of the time inputs.[9] As the set of estimators that we consider encompasses the most widely used econometric techniques in this literature, finding a ranking that does not depend on the chosen estimator would be extremely encouraging. Such a ranking, if it exists, implies that a reallocation of time use can enhance child development.

Some of our estimators are demanding in terms of data. In particular, except for the CT model, they all require panel data. But children included in one wave of our sample are not always included in the other waves, as they may have missing diary data in some years. Likewise children in the wave 2 sample are not always in the wave 1 sample. As a result, if we want to compute the CV estimator using all three waves we would be left with only about 200 observations. Given that we use about 40 control variables on the right hand side, there would be few degrees of freedom left. For this reason we decided to use only waves 1 and 2 (the largest ones) in our main analysis. Hence, the results in section 4 are obtained using the wave 2 test scores and the wave 1 and 2 time inputs and controls. In the Appendix we also show some of the results obtained using waves 2 and 3. We do not attempt to use all the three waves at once because the sample size would

[9] Of course, such a robust ranking is not necessarily the true one, as it is possible that all these estimators are inconsistent. For the same reason, a ranking which is rejected by one or more estimators is not necessarily false.

be too small. Since the MRT test score was not administered at wave 1 we cannot, in principle, compute the Value Added (VA, CV) and Fixed Effect (FE) estimators for this test. Instead, we use the Who am I? Test as a proxy for the lagged MRT test score. In other words, the wave 1 WAI test proxies for lagged ability, rather than the lagged MRT test. The results in the VA, FE and CV columns should be interpreted accordingly.

Finally, it would also be natural to consider an IV approach. However, as discussed earlier, we would need to find $K - 1 = 8$ valid instruments for the time inputs. This is not a feasible task in our application. If our main concern is the endogeneity of the time inputs arising from the correlation with the scalar μ_i, it is more practical to attempt to control or proxy for μ_i using one of the 5 common estimators described here.

4 Results

Tables 10-14 present our estimation results for cognitive and non-cognitive skills. Because the nine time inputs are collinear, we take educational activities with parents (*ped*) as the omitted category. Hence, the coefficients of the other $K - 1$ time inputs should be interpreted as their effect *relative to* that of educational activities with parents. Stars indicate whether these relative effects are significant at the 5 and 10 percent levels. We also report the F-test for the null hypothesis of equality of all the wave 2 time input coefficients.

Of course, the estimates in Table 10-14 do not directly show the ranking of the K time inputs: they do not show whether, for instance, time spent using media has a statistically different effect from time spent in social activities. To fill this gap we construct a second set of tables (see Appendix Tables A-3-A-4), where in the left column the time inputs are ranked from most to least productive, and where the cells show the difference between any pair of time inputs together with its statistical significance. Thus, the coefficients in these tables are independent of which time input is the omitted category. Next, we discuss separately the results for cognitive and non-cognitive skills.

4.1 Cognitive Skills

4.1.1 Peabody Picture Vocabulary Test (PPVT)

Table 10 shows the estimated coefficients for the PPVT test score, while Table A-3 describes the ranking of the time input coefficients. With the exception of the FE estimator we reject the hypothesis that the wave 2 time inputs are equally productive. Educational activities with parents (*ped*) and with adults other than parents (*oed*) appear to be the most productive inputs. That is, in Table 10 the coefficients on other activities are typically negative, implying that they are less productive than *ped* and *oed*. And in Table A-3 *ped* and *oed* rank as the top two time inputs for all estimators except fixed effects.

The problem with fixed effects is that the estimates are too imprecise (due to the efficiency loss that results from differencing) for the rank differences to be significant. Still, the point estimates imply that educational time with adults are among the most productive inputs.

On the other hand, time spent in general care activities with parents (*pcr*) or with other adults (*ocr*) are generally found in the bottom half of the ranking. The results have clear implications for the impact of time reallocations. For instance, the CT estimator suggests that one more hour a week spent in educational activities with parents (*ped*) rather than in general care (*pcr*) would increase the PPVT test score by 0.034 standard deviations. It is also noteworthy that time spent using media (*mda*) is a more valuable input than time in before/after school care (*sch*).

Among the control variables, the estimate of the parental education coefficient is consistently positive implying that an extra year of education raises scores by about .06 to .07 standard deviations across estimators. The exception is fixed effects where the education coefficient is imprecisely estimated and has the wrong sign. Girls score consistently lower than boys on the PPVT by .10 to .20 standard deviations. Most of the other controls have the expected sign but they are not always significant depending on the estimator.

The coefficient on the lagged test score is about 0.31 and highly significant in both the VA and CV models. Other lagged control variables do not seem to be especially important: they are jointly significant but the adjusted R-squared does not increase much when they are added. Nevertheless, in the CU and CV models the lagged coefficient on mother effective discipline is positive and quantitatively large.

To get a sense of how important time allocation is relative to the background variables (like parental education) we consider the following comparison: according to the CT estimator, the effect of having 2 more hours a week in educational activities with parents, rather than 1 hour in general care with other adults (*ocr*) and 1 hour in social activities (*soc*), is a 0.040+0.027=0.067 standard deviation increase in the PPVT score. This is about the same as the 0.063 standard deviation increase produced by one additional year of parental education.

4.1.2 Matrix Reasoning Test (MRT)

Table 11 shows the results for the MRT test, while Table A-4 presents the ranking of the time input coefficients. Overall the results are quite similar to those for the PPVT test. For instance, educational activities with parents (*ped*) and educational activities with other adults (*oed*) are always near the top of the rankings. Time spent in general care activities with parents (*pcr*) is generally near the bottom of the rankings. As with the PPVT, only in the case of the FE estimator do we fail to reject the null hypothesis that the wave 2 time inputs are all equally productive (p=.116).

According to the CT estimator, the effect of having 2 more hours a week in educational activities with parents, rather than 1 hour in general care with other adults (*ocr*) and 1 hour in social activities (*soc*), is 0.016+0.019=0.035. This is again comparable to the 0.039 standard deviation increase produced by one additional year of parental education. And, as with the PPVT, the lagged control variables are statistically significant, but their inclusion has little impact on the adjusted R-squared.

However, there are also some differences from the PPVT test score results. For example, time spent in before/after school care always ranks higher for the MRT test score than for the PPVT, while time sleeping/napping now ranks consistently as the least productive input (Of course, all the results only apply within the range of variation in the data: obviously one could not increase scores by substituting all sleep time with educational time).[10] Among the control variables, the child's gender is no longer significant, but child age is (older children scoring higher). The coefficient on the lagged score is large and highly significant, even though we are actually using the WAI test score rather than the lagged MRT score. This result suggests that lagged ability is still a good predictor for current test scores. The lagged indicator of mother effective discipline is no longer significant.

4.2 Non-Cognitive Skills

4.2.1 Behavioral Problems

Table 12 show the results for the index of behavioral problems (ordered so a higher score means fewer problems). The findings for this dimension of non-cognitive skill are very different from those for cognitive skills. With the exception of the CV estimator, the F-test provides little evidence of significant differences in the effect of the time inputs. For this reason we omit the supplementary table that describes the ranking of the time inputs. Among the control variables, parental education is never statistically significant, and girls have much better scores than boys. The coefficient on mother effective discipline is now consistently positive and quantitatively large across all five estimators (meaning more effective discipline leads to fewer behavioral problems). The lagged behavioral test

[10]Table 4 shows that at wave 2 the average child was spending 76.43 weekly hours in bed, or about 11 hours a day, with a standard deviation of 5.34 hours per week, or .76 hours per day. Thus, a two standard deviation range of sleep hours is roughly 10 1/4 to 11 3/4 per day.

score is more important than for cognitive skills, suggesting there is more persistence in the index of behavioral problems than in cognitive skills.

4.2.2 Good Relationships

The findings for the index of good relationships are reported in Table 13. The results are similar to those for behavioral problems. There is little or no evidence that the time allocation matters for this dimension of non-cognitive skill. Girls score better than boys, mother effective discipline has a positive effect on the index, and the lagged score is statistically significant and large in magnitude. The main difference with the index of behavioral problems is that now the factor capturing mother warmth is also very important.

4.2.3 Emotional Problems

Finally, Table 14 shows the results for the index of emotional problems (where a higher score means fewer problems). Consistent with the other two indexes of non-cognitive skills, we find that time allocation is of no importance.[11] Once again, mother effective discipline has a positive effect on the index, and the lagged score is statistically significant and large in magnitude. There is no evidence of a gender effect in this case, while children with more siblings score better. Overall, the adjusted R-squared is lower than for the Behavioral problems and Relationship indexes.

4.3 Comparison between Cognitive and Non-Cognitive Skills

The results in sections 4.1 and 4.2 indicate that the production functions for cognitive and non-cognitive skills are very different. Cognitive skills are affected by the way children's time is allocated and by parental education. The effect of re-allocating time across different activities is large, and (in the plausible scenarios we considered) comparable in magnitude to the effect of one more year of parental education. But non-cognitive skills seem insensitive to both the allocation of children's time and parental education. Instead we find they are strongly influenced by parenting style, specifically effective discipline and warmth. Adding these indicators of parenting style to the standard set of control variables does little for cognitive skills but strongly increases the adjusted R-squared for the non-cognitive ones.

[11] For the index of emotional problems, and to a less extent for the index of behavioral problems, the CV estimator's coefficient on *oed* is generally negative and very large. We refrain from interpreting this result as an indication that educational activities with adults other than parents might have a negative effect. It is possible that this coefficient is also picking up an effect of having less support from parents.

This result on the importance of parenting style for non-cognitive skills appears to be new in the economics literature.[12] Nevertheless, it aligns with previous studies in Developmental Psychology which found that "authoritative" parenting (a warm, engaged, rational parent-child relationship) leads to fewer behavioral problems.[13] We also find that lagged scores are more predictive of non-cognitive skills, suggesting stronger persistence in non-cognitive skills (i.e. behaviors) than in cognitive skills, at least at young ages.

4.4 A Formal Test of Rankings

The main advantage of our study is the use of 24 hour time diaries. This allows explicit characterization of the trade-off between alternative activities. The results in section 4.1 show that children's time allocation affects their cognitive development, while having little impact on their social and emotional development. Therefore, in this section we focus on cognitive skills alone, and investigate whether the data support a ranking(s) of the time inputs that cannot be statistically rejected across estimators.

We begin by testing the hypothesis that educational activities with parents (generally ranked at or near the top according to our point estimates), is more productive than three other inputs generally ranked in the bottom half: time in general care with parents or other adults and time sleeping/napping. Formally, our test can be written as:

$$H_2: \ \beta_{ped} \geq \{\beta_{pcr}, \beta_{ocr}, \beta_{bed}\}$$
$$\text{vs}$$
$$H_1: \ \{\beta_{ped}, \beta_{pcr}, \beta_{ocr}, \beta_{bed}\} \in \mathbb{R}^4 \tag{3}$$

The implementation of this type of test is complicated by the fact that the null hypothesis contains a number of inequalities. Conventional two-sided and one-sided multivariate tests are not designed to address the hypothesis in (3). Wolak (1987, 1989) develops a test for examining the validity of linear inequality constraints on the parameters of linear econometric models. His procedure involves three steps. First, one solves

$$\min_b (Y - Xb)'(Y - Xb) \text{ subject to } Rb > r \tag{4}$$

[12] Dooley and Stewart (2007) only look at non-cognitive skills while Cosconati (2009) looks at the effect of one aspect of parenting style (i.e., time use constraints, or curfews) on cognitive skills. Bjorklund et al. (2011) investigate the determinants of siblings correlation in income. However, we are not aware of any prior study that both: (i) uses broad measures of parenting style, and (ii) compares effects on cognitive vs. non-cognitive skills.

[13] Weiss and Schwarz (1996) find that authoritative parenting also leads to higher school grades, which contradicts our results on the PPVT and MRT. However, they study older adolescents, not young children.

where X is the matrix of covariates (i.e. time inputs and parental background variables) and $Rb > r$ expresses the inequality constraints. Second, we compute the Wald statistic, using the restricted and unrestricted estimates together with the unrestricted estimate of the variance-covariance matrix. However, the Wald statistic has a $\overline{\chi^2}$ distribution: a weighted average of χ^2 cdf's where the weights have to be computed or simulated.[14] The third and final step involves deriving the weights and computing the p-values accordingly.

Testing (3) is not sufficient however. Even if H_2 is not rejected, the null hypothesis could hold with equality. Because of the weak inequalities, the null hypothesis in (3) is a test for educational activities with parents being *no worse* than the other three time inputs (pcr, ocr, bed). Therefore, we complement (3) by testing the null hypothesis of equality versus weak inequality:

$$H_0: \ \beta_{ped} = \beta_{pcr} = \beta_{ocr} = \beta_{bed}$$
$$\text{vs}$$
$$H_2: \beta_{ped} \geq \{\beta_{pcr}, \beta_{ocr}, \beta_{bed}\} \tag{5}$$

Wolak (1987, 1989) also shows how to implement the test in (5). Hereafter we refer to the test in (3) as the Inequality vs Unrestricted (IU) test while we refer to the test in (5) as the Equality vs Inequality (EI) test. If we cannot reject the null in the IU test but we reject the null in the EI test then we can conclude that H_2 holds with at least one strict inequality. In our context, that would imply that educational activities with parents is *no worse* than the other three activities (i.e. time in general care with parents or other adults and time in bed), while at the same time being *better* than at least one of them. We also test a few permutations of the time inputs to see whether multiple rankings could be consistent with the data.

Tables 15 and 16 show the results for the PPVT and MRT test scores respectively. The numbers in the table are the Wald statistics obtained by solving (4) subject to either (3) or (5), giving the the IU and EI tests respectively. A Wald statistic of zero corresponds to the case where the restricted and unrestricted estimates are identical. Stars indicate whether the Wald statistics are significantly different from zero, with the p-values calculated as explained above.

The first ranking tested in Tables 15-16 (Rnk1) is the one defined in (3). For both the PPVT and MRT test scores, the Wald statistic for the IU test is always zero or approximately zero, indicating that this ranking is strongly supported by the data. The Wald statistic for the EI test is always positive and statistically significant, indicating

[14]Close form solutions for the weights exist only for $rank(R) \leq 4$.

that the hypothesis of equality is strongly rejected. Together, these two results support the hypothesis that educational activities with parents are more productive than time in general care with parents or other adults and time in bed.

In the second ranking (Rnk2), we replace educational activities with parents (*ped*) with educational activities with other adults (*oed*). This time input was also often ranked near the top in Table A-4. The Wald statistic for the IU test is again equal to zero for both the PPVT and MRT tests and for all estimators. But this time the statistic for the EI test is smaller and never significant. This is probably due to the relatively low variation in educational activities with other adults (see Table 4), which causes the coefficient on *oed* to be imprecisely estimated.

Next, we extend our test by including time in before/after school care in our set of "inferior" time inputs (alongside time in general care with parents or other adults and time in bed). We refer to the rankings where educational time with parents or with other adults are the "superior" inputs as Rnk3 and Rnk4 respectively. These tests involve one additional inequality than the test in (3) so the Wald statistics can only be larger. The results for Rnk3 and Rnk4 are little changed from the previous results for Rnk1 and Rnk2: the Wald statistics for the inequality tests are zero or approximately zero, so we never reject the ranking. The equality test is rejected for educational activities with parents (the only exception being the FE estimates for the MRT score), but not for educational activities with other adults. Thus, the LSAC data suggests that one could improve children's cognitive test scores via a reallocation of time that increases time in educational activities with parents while reducing time in general care activities, in bed or in before/after school care. This conclusion holds under all estimators.

Since the data back Rnk1 and Rnk3, we proceed to test the stronger hypothesis that educational activity with parents (*ped*) is more productive than time using the media (*mda*), and that time using the media is more productive than time in general care with parents or other adults and time in bed. We call this Rnk5. The hypothesis that time spent using media is among the most productive activities seems consistent with table A-3 but less so with A-4. Formally, the inequality test can be written as:

$$H_2: \ \beta_{aed} \geq \beta_{mda} \geq \{\beta_{pcr}, \beta_{ocr}, \beta_{bed}\}$$

$$\text{vs}$$

$$H_1: \ \{\beta_{ped}, \beta_{mda}, \beta_{pcr}, \beta_{ocr}, \beta_{bed}\} \in \mathbb{R}^5 \qquad (6)$$

while the equality test that is analogous to (5) follows accordingly. The test in (6) involves two more inequalities than the test in (3). Nevertheless, as we see in Tables 15-16, we still obtain small Wald statistics and the hypothesis of inequality is never rejected. At the same time, the hypothesis of equality is always strongly rejected. These results indicate that parents could improve cognitive outcomes by substituting media time for general care with parents or other adults and time in bed; or, better yet, by increasing time in educational activities with parents.

Finally, we add one more inequality by adding time in before/after school care to the set of "inferior" inputs (i.e. time in general care with parents or other adults and time in bed). We call this Rnk6. By transitivity this also implies that educational activities with parents are the most productive activities. This time the null hypothesis holds for the PPVT test, but it is sometimes rejected for the MRT score. This is an interesting result: some parents may view having their child home using media as a normal alternative for before/after school care. The LSAC data indicate that this substitution might benefit the child's verbal skills (PPVT) but not logical skills (MRT).

4.5 Functional Form and Optimal Allocation

All our models specify a linear relationship between the time inputs and the children's skills. Thus, the results should be interpreted at the margin: i.e. they measure the effect of re-allocating children's time within the range of variation provided by the data. The effect would eventually break down for large re-allocations because the marginal products cannot be constant, especially since time is a finite resource.

We checked the robustness of our results to functional form assumptions by re-estimating all models in log form ($ln\ Y_{ia} = TI'_{i\{K\times a\}}\beta_{\{K\times a\}} + PB'_{i\{G\times a\}}\delta_{\{G\times a\}} + e_{ia}$) and then replicating the ranking tests of Tables 15-16. These results are reported in Tables A-5 and A-6 in the Appendix. The results are virtually unchanged. We also tried to re-estimate the models using a 2^{nd} degree polynomial in the time inputs ($Y_{ia} = TI'_{i\{K\times a\}}\beta_{\{K\times a\}} + TI^2_{i\{K\times a\}}{}'\varsigma_{\{K\times a\}} + PB'_{i\{G\times a\}}\delta_{\{G\times a\}} + e_{ia}$). However, the estimates become very imprecise and the adjusted R-squareds did not improve.

It is also important to recognize that, if parents are making input choices optimally, then our estimates imply nothing about it being optimal to have any change in behaviour. While our study is informative about the productivity of each time input, optimal allocations also depend on input prices. Marginal products should not be expected to be equalized at the optimum. Our results are nevertheless of interest since incomplete information about the production function may cause sub-optimal decisions:

- for parents, in the way they allocate their children's time;
- for policy makers, in the way they use levers at their disposal (e.g. child care subsidies, parental leave policies) to change the time input prices so as to enhance

child development.

4.6 Model Uncertainty

When many models are initially considered, all of them defensible, the analyst has three main options. The first is to pick one model and adopt the conclusions that flow from it rather than from the other defensible models. But, as we explained earlier, we eschew any attempt to choose a "best" model, as any criterion we could use would necessarily be controversial. The second option is to present the analyses based on all the plausible models without choosing between them. This is the idea of sensitivity analysis and it is our preferred option here. The third possibility is to take account explicitly of model uncertainty, for instance through Bayesian Model Averaging (BMA). The logic of Bayesian inference says that one should obtain results from every model under consideration, average them and then draw the conclusions from the averaged results. Suppose that we want to use the data D to compare competing hypotheses, which are represented by the S statistical models $M_1, \ldots, M_S$. Then, by Bayes' theorem, the posterior probability that M_s is the true model (given that one of the $M_1, \ldots, M_S$ models is the true one) is

$$p(M_s|D) = \frac{p(D|M_s)p(M_s)}{\sum_{\ell=1}^{S} p(D|M_\ell)p(M_\ell)}$$

one can then use $p(M_s|D)$ to weight the model. We implement BMA following Raftery (1995) and Brock and Durlauf (2001). We put all the models on an equal footing a priori, so that $p(M_s) = \frac{1}{S}\ \forall s$, where $S = 5$ in our case. We then approximate $p(D|M_s) \approx \exp(\frac{1}{2}BIC_s)$ where BIC is the Bayesian Information Criterion. Then

$$p(M_s|D) = \frac{\exp(-0.5BIC_s)}{\sum_{\ell=1}^{S} \exp(-0.5BIC_\ell)}$$

Table 9 illustrates the results for the two cognitive skills. In both cases the posterior odds favour the Contemporaneous + Lagged Inputs + Lagged Test (CV) model strongly: the weight is 1. This would suggest using the estimates from the the CV model alone.

While the ranking of time inputs is very similar across estimators, such that focussing on the CV model alone would not alter the main conclusions (only the FE estimator stands out on some occasion) we still take the BMA results with caution. BMA assumes that one of the models is the "true" one, something we cannot be sure of, as explained in section 3.6. Moreover, the implication of BMA is to focus on 1 set of (averaged) results, rather than testing their sensitivity across different specifications. It is not clear to us that model averaging is a better way to deal with model uncertainty. We still believe

Table 9: Weights in Bayesian Model Averaging

	PPVT				
	CT	VA	FE	CU	CV
BIC	3.0321e+03	2.5076e+03	4.1671e+03	1.4066e+03	1.3204e+03
$p(M_s\|D)$	0	0	0	0	1
	MRT				
	CT	VA	FE	CU	CV
BIC	3.1553e+03	2.7898e+03	4.1986e+03	1.4414e+03	1.4014e+03
$p(M_s\|D)$	0	0	0	0	1

that sensitivity analysis is more appropriate in our context.

4.7 Other Robustness Checks

In tables A-7 and A-8 in the Appendix we present the Wald statistics obtained when using waves 3 and 2 rather than waves 2 and 1. The results point in a similar direction. Rnk1-Rnk6 *IU* tests are rarely rejected and the equality *EI* tests are often rejected for the PPVT score. In contrast to the tests in Table 16 however, in Table A-8 the *EI* tests often fail to reject for the MRT score. Unfortunately, the smaller sample size adversely affects the power of the tests. This is particularly true when using the CU and CV estimators for which we have no more than 200 observations.

We also tried to impute some of the incomplete time slots using the *where* and *who with* entries. We did so whenever there were only a handful of incomplete slots in the diary. While sample size increased there was no substantial change in the results. Therefore we chose to present the results without the imputed time slots.

Finally, a referee suggested that we instrument for the lagged test scores in the value added models: VA and CV. This suggestion follows from the idea that test scores may measure innate ability with error. Instrumenting for the lagged test scores is straightforward in the case of the cognitive ability tests, since all we need is another test score that is correlated with the lagged one. In the case of the PPVT score, we use the Who Am I test as an instrument for the lagged PPVT. In the case of the MRT score, we use the lagged PPVT as an instrument for the Who Am I. Using instrumental variables leads to larger estimates of the lagged test score coefficients, but more importantly it has little effect on the time use coefficients and the corresponding ranking tests. Finding instruments for the lagged non-cognitive test scores is more difficult. Since these are derived from factor analysis they are orthogonal by construction. Therefore we were unable to implement IV for the behavioural test results.

4.8 Heterogeneity

In this section we explore whether the results are heterogeneous across sub-groups. We report the results of the IU and EI tests only.

4.8.1 Child Gender

We first split our sample of children according to their gender. Table 17 reports the average number of hours in each activity by gender. Girls spend more time than boys in educational activities with parents and in bed. Boys spend more time using media. These differences are statistically significant at the 1% level. To test for heterogeneity in the production function across genders we re-estimate all the models for boys and girls separately. Therefore, all the coefficients, and not just those on the time inputs, are allowed to vary across gender. Tables 18 and 19 report the Wald statistics for the input ranking tests, using the PPVT and MRT test scores respectively.

For the PPVT test, there are no large differences between boys and girls, and the results are similar to the those obtained using the whole sample (Table 15). One exception is given by the small and rarely significant Wald statistics obtained when using Fixed Effects, where power is likely quite low given the small sample size.

For the MRT test, the results for girls are relatively close to those obtained when using the whole sample (Table 16). But in the case of boys the EI tests rarely reject when using the CU and CV estimators. This differs from the findings for girls or the whole sample. The implication of this is that the evidence that educational time with parents is superior to the other inputs is much weaker for boys than for girls. This pattern is not replicated when using the CT and VA estimators however. We do not have a clear intuition to explain this difference based on gender. But, since the CU and CV estimators include the lagged time inputs, this result might suggest that boys are more sensitive than girls to early childhood investments.

4.8.2 Mother's Education

Next, we split the sample based on mother's education: (1) mothers who have completed at most a Certificate degree vs (2) mothers with an Advanced Degree or above.[15] While the full sample results imply that time in educational activities with parents is beneficial for cognitive development, it is possible that this is only true for more highly educated mothers. Intuitively, the more educated the mother, the better the "quality" of her

[15]Table 7 in section 2.2 describes the distribution of mothers education. In the Australian education system an Advanced Degree requires the completion of Year 12, and it is classified just below a Bachelor Degree. We do not split the sample into more than the two sub-groups because the sample size of some sub-groups would be very small.

time. But on the other hand, more educated mothers might also ensure better quality substitutes for maternal time.

The statistics in Table 20 show that children with more educated mothers spend more time in educational activities with parents and more time in social activities. On the other hand, they spend 1.6 fewer hours per week using media. These differences highlight the importance of controlling for parental education in order to obtain consistent estimates of the effect of time inputs.

Table 21 illustrates the results for the PPVT test score. For both high and low education mothers we find evidence that time in educational activities with parents is more productive than other time inputs. But the evidence is weaker for the less educated mothers. That is, in the top panel of Table 21 there are a few cases where the EI test does not reject equality of the time inputs coefficients.

In the case of the MRT test, Table 22, we do not find much difference by education. The overall pattern of educational activities with parents being better than media, which in turn is better than the other activities, generally holds regardless of the mother's education. In summary, we find evidence that educational time with parents is superior to other time inputs for both the PPVT and the MRT. But the evidence from the MRT is more clear.

5 Conclusion

The aim of this paper is to investigate the determinants of child cognitive and non-cognitive development using a much richer specification of the production function than in prior work. Rather than examining the effects of only one or two time inputs at the time - as has been common - we attempt to look at all the child's activities within a representative week. By doing so we characterize the trade-off between all alternative activities to which a child is exposed. This richer specification of inputs is made possible by the LSAC diary data whose purpose is to collect a detailed record of all of a child's activities in a week, as well as collecting a rich set of measures of other inputs to child development.

A few important conclusions can be drawn from the findings of this study. One key result is that cognitive skills are affected by the way children's time is allocated. Educational activities such as reading a story, being talked to or helping with chores are the most "productive", particularly when they are done with the parents. A reallocation of children's time which favors this kind of activity by substituting away from time in general care, bed or before/after school care would have a positive effect on skills. The effect is estimated to be quantitatively large, comparable to the effect of increasing parental education. This result is robust to different identification assumptions - that is, it holds for all five major approaches to estimating the skills production function discussed by Todd and Wolpin (2003, 2007).

Perhaps more surprisingly, time spent using media such as TV and computers does not seem necessarily detrimental to development. For example, for reading skills, it is at least as productive as time in before/after school care.[16] We stress that our estimates of the productivity of inputs hold “at the margin”, since we use a linear approximation to the production technology and our data vary in a limited range. Obviously one would not want to extrapolate the results beyond the range of variation in the data.

When breaking the sample into sub-groups we find that there are differences in the way time is allocated for boys and girls. Girls spend more time than boys in educational activities with parents and also in bed. Boys spend more time using media. Also, our results on educational activities with parents being superior to other inputs are more robust for girls than for boys.

The data also show that children with more educated mothers spend more time in educational activities with parents and in social activities. On the other hand, they spend about 1.6 hours less per week using media. We find some evidence that time in educational activities has a larger positive effect on reading skills if the mother is more educated, but the evidence is quite weak. Thus, the superiority of educational time with parents over other inputs appears to hold even for less educated mothers.

Another key finding is that the production functions for cognitive and non-cognitive skills are very different. With respect to non-cognitive skills like behavioral problems, social skills and emotional problems, the allocation of children’s time is not important. Instead we find that these skills are strongly influenced by parenting style, particularly mother’s warmth and effective discipline. A parenting style that combines effective (but not harsh) discipline with parental warmth and affection leads to the best behavioral outcomes. Either leniency or excessive harshness in discipline lead to worse outcomes.

In discussing the determinants of child development, it is useful to compare our results with previous studies in the fields of Developmental Psychology, Education, Medical Science and Sociology.[17] However, we could not find a comparable time use study where activities are ranked and the trade-offs made explicit. Thus, our study seems rather novel

[16]Although we find that time using the media can be productive, we do not know what kind of TV or computer program the children use. The data only tells us how much time is spent on it but not what they do with the media. Still, these results indicate that the effect of media is an important area of research. There are a few recent papers that look at the effect of being exposed to media. See for instance Gentzkow and Shapiro (2008), Malamud and Pop-Eleches (2010), Vigdor and Ladd (2010) and Fiorini (2010). However, these papers have little or no information on the content of the media.

[17]Shonkoff, Phillips, and Council (2000) offers an extensive review of the research approaches and findings in those fields.

in its approach, making comparisons difficult. We are certainly not the first to stress the importance of parental time. But our study highlights that it is difficult to find an equally beneficial substitute. Similarly, the literature is devoting a growing amount of attention to the role of media, but there is little discussion of the trade-off between media and alternative inputs.[18]

The non-Economics literature has also long stressed the link between parenting style on the one side and cognitive and non-cognitive development on the other. Our paper shows that the evidence of a link with non-cognitive skills is robust to a range of estimators commonly used in econometrics. However, we do not find evidence of any link with cognitive skills. We suspect that part of the explanation may be the measurement of parenting style. In our data, information on parenting is limited to traits that we label maternal warmth and discipline. This is consistent with classic, early studies of childrearing that sought to identify styles of parenting that promoted competent behavior in preschoolers (i.e., a child who is happy, self-reliant, self-controlled, friendly, and cooperative as distinct from withdrawn or immature).[19] Nevertheless, part of this literature has more recently extended the analysis to traits like contingency, reciprocity and restrictiveness that have been found to matter for cognitive skills, but for which we have no direct measure.[20]

Our findings suggest the importance of further research in a number of areas. First, the literature on child development can benefit from collecting and analysing time use data. Our result indicate that these time inputs can be just as important as the parental background characteristics and goods inputs that have received most of the attention in prior work. Second, the trade-off between inputs, whether these are time allocations or goods, is often overlooked. As a consequence, some studies might convey limited and potentially misleading information. When possible, more emphasis should be placed on such trade-offs. Third, the effect of time using media on child development deserves further consideration. While children are increasingly exposed to a variety of media, little is known about how different media and their content affect child development - at least not relative to other inputs. Our findings, together with previous studies, indicate that media can be an important input in the production function. Finally, the role of parenting style has also received scant attention in Economics. However, our results combined with earlier research in Developmental Psychology indicate that it is of substantial importance, at least for non-cognitive skills.

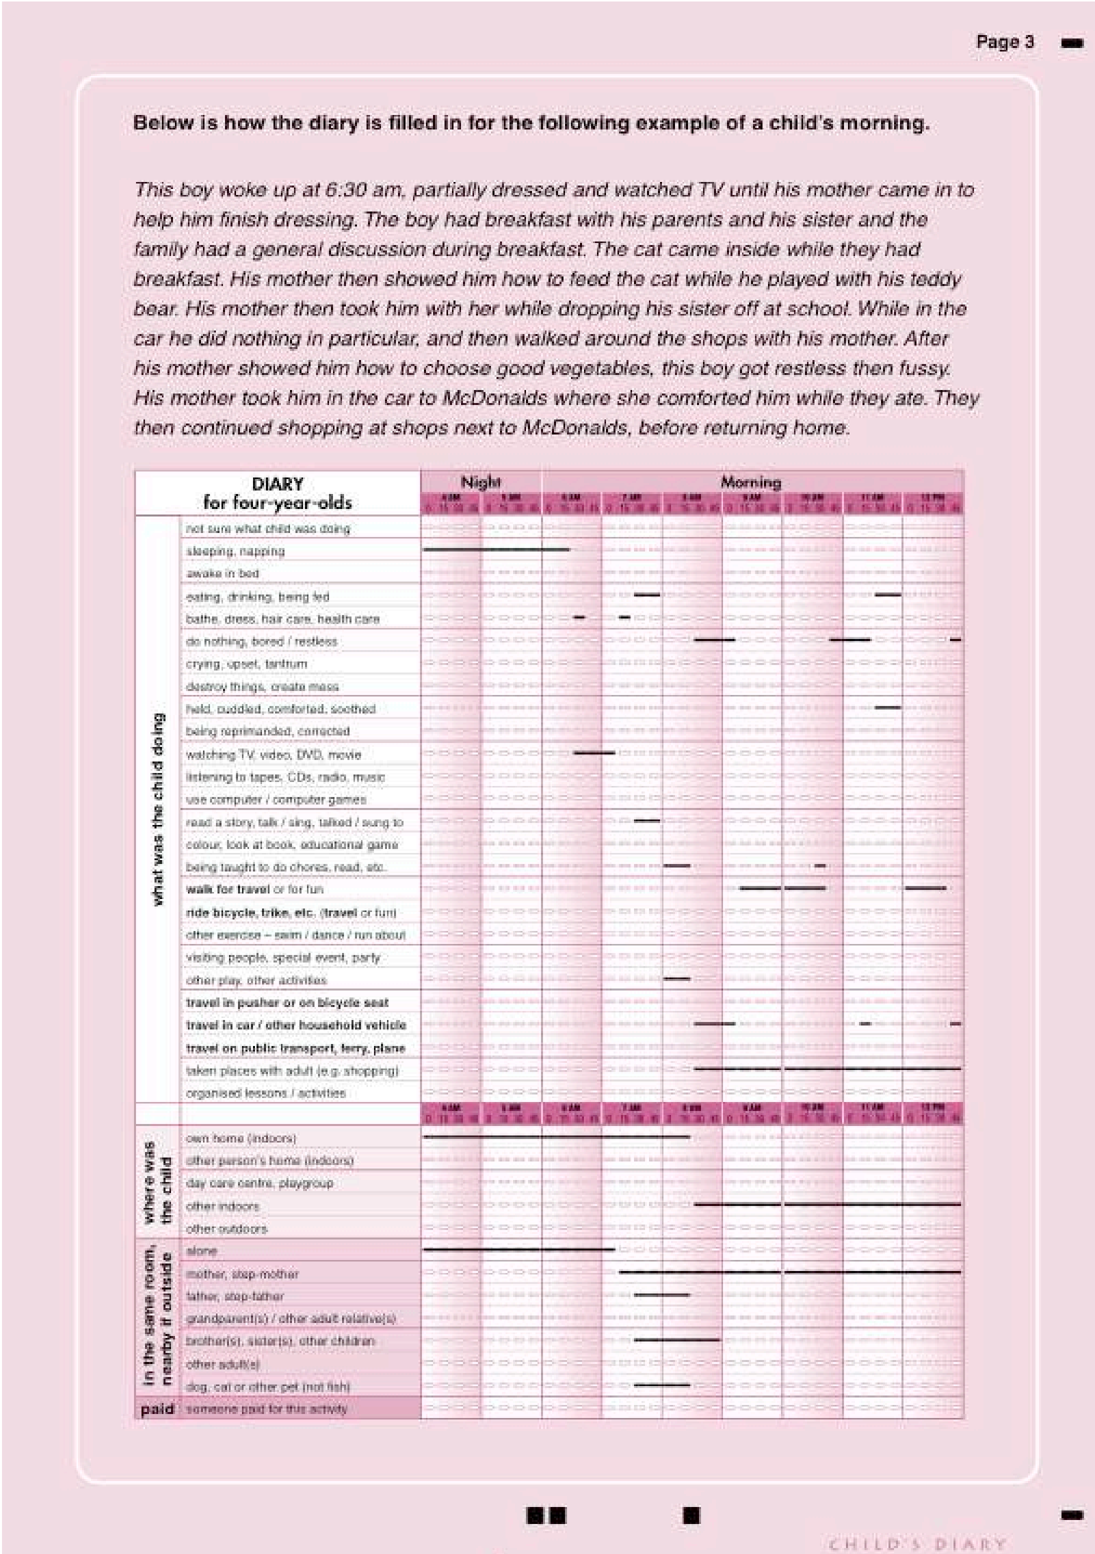
Brother(s), sister(s), other children						
Other adult(s)						
Dog, cat or other pet (not fish)						
Was this activity done for or as part of homework						

Figure A-1: Time Use Diary at Wave 2 and 3



Page 3

Below is how the diary is filled in for the following example of a child's morning.

This boy woke up at 6:30 am, partially dressed and watched TV until his mother came in to help him finish dressing. The boy had breakfast with his parents and his sister and the family had a general discussion during breakfast. The cat came inside while they had breakfast. His mother then showed him how to feed the cat while he played with his teddy bear. His mother then took him with her while dropping his sister off at school. While in the car he did nothing in particular, and then walked around the shops with his mother. After his mother showed him how to choose good vegetables, this boy got restless then fussy. His mother took him in the car to McDonalds where she comforted him while they ate. They then continued shopping at shops next to McDonalds, before returning home.

DIARY for four-year-olds

Night | Morning

4 AM | 5 AM | 6 AM | 7 AM | 8 AM | 9 AM | 10 AM | 11 AM | 12 PM

what was the child doing:
- not sure what child was doing
- sleeping, napping
- awake in bed
- eating, drinking, being fed
- bathe, dress, hair care, health care
- do nothing, bored / restless
- crying, upset, tantrum
- destroy things, create mess
- held, cuddled, comforted, soothed
- being reprimanded, corrected
- watching TV, video, DVD, movie
- listening to tapes, CDs, radio, music
- use computer / computer games
- read a story, talk / sing, talked / sung to
- colour, look at book, educational game
- being taught to do chores, read, etc.
- **walk for travel** or for fun
- **ride bicycle, trike, etc.** (**travel** or fun)
- other exercise – swim / dance / run about
- visiting people, special event, party
- other play, other activities
- **travel in pusher or on bicycle seat**
- **travel in car / other household vehicle**
- **travel on public transport, ferry, plane**
- taken places with adult (e.g. shopping)
- organised lessons / activities

where was the child:
- own home (indoors)
- other person's home (indoors)
- day care centre, playgroup
- other indoors
- other outdoors

in the same room, nearby if outside:
- alone
- mother, step-mother
- father, step-father
- grandparent(s) / other adult relative(s)
- brother(s), sister(s), other children
- other adult(s)
- dog, cat or other pet (not fish)

paid: someone paid for this activity
